

**Fig. S1.** (a) Left: Psoriatic erythroderma (before treatment with infliximab). Right: Clinical appearance 3 months after treatment with infliximab. (b) A second skin biopsy from the buttock showed features of psoriasis: confluent parakeratosis, hypogranulosis and thinning of the epidermis on the papillary dermis. Vacuolar degeneration of the basal layer and perivascular infiltration of lymphocytes and eosinophils in the upper dermis were also observed (haematoxylin and eosin stain) (original magnification  $\times 100$ ).
