Letters to the Editor

may be formed and released from macrophages. Parallels to the pathogenesis of silica-induced scleroderma are given, as observed in 111 patients in our department (14).

As silica cannot be removed from the body, its precipitating effect cannot be stopped. This indicates that the clinical course is that of classical autoimmune diseases, with progressions and remissions. The therapy has to be in line with these facts and has to be adjusted according to the criteria of the clinical activity of the disease. The best way to prevent this type of SLE is to minimize the exposure to silica.

Centroblastic-centrocytic Lymphoma Arising at the Site of Previous Herpes Zoster Eruption

Sir,
The development of a skin disorder at the site of an unrelated, already healed disease is known as isotopic response. We describe a patient in whom a centrocytic-centroblastic lymphoma developed at the site of a previous herpes zoster.

CASE REPORT

In 1994, a 58-year-old Caucasian man had a herpes zoster eruption on the left antero-lateral thoracic region. Three months later, asymptomatic, firm, brown-red papulonodular lesions, 0.5–2.0 cm wide, began to develop on the zoster site, where only a pigmented macule had remained (Fig. 1). Axillary lymph nodes and spleen were not palpable. Laboratory tests, including complete blood cell counts, liver and renal function, were within normal ranges. No concurrent extracutaneous disease findings were detected by chest radiography, computerized abdominal tomography and echography.

Histopathology of a nodular lesion showed a lymphoid infiltrate in the papillary and reticular dermis without epidermotropism, mainly composed of a mixed centrocytic/centroblastic population with a conspicuous follicular pattern. Collagen bundles were in part dissociated by the infiltrate. Immunohistologically, most of the lymphoid cells stained with anti-CD20 monoclonal antibodies and a few of them with anti-CD3 monoclonal antibodies. Immunocytochemistry showed a monoclonal proliferation of cells staining for mu and kappa chains.

Treatment with natural interferon alpha (3 MU three times a week IM) was initiated, and the lesions cleared completely in 8 months. The drug was then stopped and, 3 months later, the tumour relapsed in the same area. The lesions partly cleared after a second course of interferon therapy at the same dosage.

DISCUSSION

The term isotopic response refers the occurrence of a new skin disorder at the site of another one, already healed and unre-

Surgical Treatment of Pemphigus Vulgaris Localized to the Genital Mucosa

Sir,

Cases of pemphigus vulgaris located on a single mucosa, sometimes preceding by months or even years a more diffuse development of the disease, are not unusual but the oral mucosa is nearly exclusively involved in such observations.

We here report an original observation of an immunologically typical, unilesional pemphigus vulgaris located on the foreskin in a middle-aged man. The patient was completely cured by a limited surgery, without relapse after a 3-year follow-up.

CASE REPORT

A 47-year-old man was first referred to our institution in 1993 for chronic, bullous and erosive lesions of the foreskin of 2 years’ duration. Clinically, a limited area of the balano-preputial fold and of the free foreskin mucosa was involved, with a number of small erosions ranging from 1–2 mm in diameter. The patient denied taking any long-duration medication and no other mucous membrane manifestations had ever been present. The mucocutaneous and general examination were otherwise normal and no Nikolski’s sign was present. ESR, full blood count, comprehensive chemical panel, liver tests and renal function were all normal. Two different biopsy specimens taken on the margin of the erosions revealed a suprabasal cleavage with a typical acantholytic picture, along with an important mononucleated infiltrate of the upper chorion (Fig. 1). Direct immunofluorescence showed the deposition of intercellular IgG and C3c in the epithelium;
