SHORT COMMUNICATION

A Case of Miliary Tuberculosis Presenting with Whitlow of the Thumb

Accepted Nov 10, 2015; Epub ahead of print Nov 11, 2015

Tuberculosis remains a major public health concern, accounting for millions of cases and deaths worldwide. In 2013, an estimated 9.0 million people developed tuberculosis and 1.5 million died from the disease (1). Among the 5.4 million new notified cases, 2.6 million had bacteriologically confirmed pulmonary tuberculosis, 2.0 million had clinically diagnosed pulmonary tuberculosis, and 0.8 million had extra-pulmonary tuberculosis (1). Extra-pulmonary tuberculosis can affect any organ of the body, and has a broad spectrum of manifestations (2). Cutaneous tuberculosis is an uncommon manifestation of tuberculosis, accounting for 0.5–2% of all extra-pulmonary tuberculosis (3). Cutaneous tuberculosis is caused mainly by infection with Mycobacterium tuberculosis complex and occasionally by infection with M. bovis or BCG vaccine. The clinical appearance of cutaneous tuberculosis can vary, depending on the exogenous or endogenous origin of the infection.

We report here an original case of disseminated tuberculosis, revealed by a whitlow, and describe our diagnostic approach, treatment and outcome. The patient provided written consent for publication of this case report.

CASE REPORT

A 75-year-old woman with a medical history of autoimmune thyroiditis treated with L-thyroxin was admitted to the emergency department with pain, oedema, erythema of the left thumb, and fever for 3 days. Her general practitioner diagnosed a whitlow and started pristinamycin with no improvement. The patient reported back pain that had started 6 months previously, associated with a vertebral fracture of T11–T12, which had been treated with corticosteroids for 3 months.

At admission, physical examination revealed an inflammatory swelling of the left thumb. The skin was tender from the base of the thumb to the thenar region. Extension of the left thumb was limited. Diagnosis of a sheath phlegmon affecting the flexor of the left thumb was established. Surgery with drainage, and co-amoxiclav treatment were performed immediately. The patient was then transferred to the infectious diseases department.

CT-scan-guided discovevertbral biopsies of T12 were acid-fast bacilli (AFB) smear-positive. Antibiotic failure on the thumb led us to perform a M. tuberculosis complex PCR from the skin biopsy, which was positive. Cultures from discovevertbral biopsies, skin biopsy and gastric aspiration proved positive for drug-sensitive M. tuberculosis. The HIV test was negative.

After 2 weeks of standard anti-tuberculosis treatment (isoniazid, rifampicin, ethambutol and pyrazinamide), fever, pain and dyspnoea all improved. Evolution of the left thumb wound was also favourable. Clinical and biological tolerance of the treatment was good. According to drug susceptibility test results, ethambutol was stopped after 1.5 months of anti-tuberculosis treatment. Isoniazid, rifampicin and pyrazinamide were prescribed for a total of 3 months, while both isoniazid and rifampicin were continued for a further 9 months. Anti-tuberculosis therapy resulted in a favourable outcome with complete resolution of the skin lesion.

DISCUSSION

In the present case, the diagnosis of disseminated tuberculosis was established because of the association of a pulmonary miliary, Pott’s disease, and a phlegmon of the flexor sheath of the thumb. Tuberculosis explains the fact...
that the sheath phlegmon evolved unfavourably despite rapid surgery and conventional antibiotic treatment.

Cutaneous tuberculosis can have various clinical manifestations. Infection can be acquired through exogenous routes from direct inoculation of *M. tuberculosis* into the skin. With this route of infection, clinical manifestations are tuberculous chancre, tuberculosis verrucosa cutis, and in some cases, lupus vulgaris. These clinical manifestations are commonly observed in healthcare workers and are difficult to diagnose because of their paucibacillary nature, leading to a high frequency of negative cultures. Cutaneous tuberculosis can also result from an endogenous infection, secondary to a pre-existing primary focus. Tuberculosis cutis orificialis, scrofuloderma, and most cases of lupus vulgaris, result from contiguous dissemination, acute miliary tuberculosis and tuberculous abscess from lymphohematogenous dissemination (3). Tuberculous abscesses, or gumma, has been described in individuals with acute miliary tuberculosis and may infrequently affect immunocompetent adults (4). These are non-tender fluctuant subcutaneous nodules. The nodules eventually penetrate the skin, resulting in the development of ulcers and draining sinuses (3, 5). Lesions may occur at any skin site, but frequently develop on the extremities. Satellite regional lymph nodes are usually not present (3, 5).

In our case, PCR and culture from the skin biopsy were positive and explained the unfavourable outcome of the wound with standard antibiotic treatment. However, the diagnosis of disseminated tuberculosis was based initially on the positive AFB-smear of gastric aspiration and of vertebral biopsies of T12, later confirmed by PCR and culture. In general, manifestations of miliary pulmonary can be acute, but are more likely to be sub-acute or chronic (9). Patients often report dyspnoea or cough, and hypoxemia is common. In the present case, the patient had a febrile dyspnoea with mild hypoxemia related to a sub-acute or chronic miliary tuberculosis. Pathogenesis is likely to be a lympho-haematogenous dissemination of *M. tuberculosis* from a pulmonary focus with embolization to vertebral bones then to the left thumb joint and the skin. This dissemination was favoured by the corticosteroids given to treat the back pain.

Treatment of cutaneous tuberculosis is the same as for systemic tuberculosis (6, 7). The therapeutic response of cutaneous lesions can be assessed clinically. Surgical treatment is not usual for the management of cutaneous tuberculosis, but is sometimes required to manage extensive or recalcitrant tuberculosis skin lesions (6, 7). The treatment duration is usually 6 months. In our case, the treatment duration was dependent on the bone involvement. We opted for a 12-month regimen (10).

In conclusion, disseminated tuberculosis can be revealed by an atypical cutaneous lesion mimicking a whitlow and can be observed in non-HIV-infected patients. This diagnosis should be considered when the outcome is unfavourable despite surgery and antibiotic treatment, notably in the context of immunosuppression.
