Peripheral blood eosinophilia has been reported to occur in a wide range of haematological malignancies including primary cutaneous lymphomas. The concurrence of lymphomatoid papulosis (LyP) with peripheral blood eosinophilia seems to be an uncommon phenomenon. Atypical lymphocytes in LyP display the phenotype of activated T-helper cells, consistently express CD30 antigen, have a Th2 cytokine profile, and secrete eosinophil-stimulating cytokines. Cases of LyP have been reported in association with myeloproliferative hypereosinophilic syndrome (M-HES) presenting the Fip1-like 1/platelet-derived growth factor receptor-α (FIP1L1-PDGFRA) fusion gene. In such cases, imatinib treatment may lead to a complete and persistent resolution of LyP lesions.

CASE REPORT

A 25-year-old man was referred to our Department in November 2011 for evaluation of a 3-year history of recurrent crops of self-healing erythematous papules and nodules with central ulceration on the lower extremities, oral mucosa and face. Biopsy had established the diagnosis of LyP. The patient reported periodical appearance of lesions that regressed spontaneously leaving residual scars. His past medical history disclosed childhood-onset asthma, allergic conjunctivitis and spontaneous leaving residual scars. His past medical history included periodical appearance of lesions that regressed spontaneously leaving residual scars. Marked eosinophilia, atypical spindle-shaped mast cells and increased reticulin fibrosis. Interstitial deletion of the 4q12 region seems to be an uncommon phenomenon.

Physical examination disclosed a firm, well-demarcated, painless, ulcerated nodule, 1.2 cm in diameter on the right aspect of the chin. Several erythematous papules and residual scars on the lower extremities were also observed. A solitary nodule with a central crust was noted on the left leg (Fig. 1a, b). No enlarged lymph nodes were detected.

Two 4-mm punch biopsies from different lesions disclosed a dense, dermal, wedge-shaped infiltrate with clusters of large atypical lymphoid cells admixed with small lymphocytes, histiocytes, neutrophils and eosinophils (Fig. 1c–f). Neoplastic cells were CD30+ and expressed mature T helper cell markers (CD3, CD2, CD5 and CD7, CD4). No expression of ALK, c-KIT or CD56 was detected. Neoplastic cells were also MUM-1+ and 60% of cells expressed Ki-67 antigen. In both biopsy specimens, an identical clonal rearrangement of the T-cell receptor (TCR) γ and β chains was detected. No T-cell clonality was detected in peripheral blood samples.

Laboratory tests disclosed massive peripheral eosinophilia (6,120/mm³), normal IgE levels, elevated tryptase (15.5 ng/ml) (NV < 13.5) and vitamin B12 serum levels (>2,000 ng/ml) (NVs: 197–866). Stools for ova and parasites were negative. Body computed tomography (CT) showed bronchial dilatation with peribronchial thickening and confluent centrolobular nodules forming a ground glass pattern. Electrocardiogram, echocardiogram and ophthalmological examination showed no abnormalities.

A bone marrow biopsy was obtained showing hypercellular marked eosinophilia, atypical spindle-shaped mast cells and increased reticulin fibrosis. Interstitial deletion of the 4q12 region seems to be an uncommon phenomenon.

Imatinib Treatment of Lymphomatoid Papulosis Associated with Myeloproliferative Hypereosinophilic Syndrome Presenting the FIP1L1-PDGFRα Fusion Gene

Fig. 1. Clinical and histochemical characteristics. (a) Ulcerated inflammatory nodule on the right side of the patient’s chin. (b) Necrotic erythematous infiltrated plaque on the leg. (c) Histopathology revealing a wedge-shaped dense inflammatory infiltrate extending from papillary to reticular dermis (haematoxylin and eosin staining (H&E); original magnification ×40). (d) Atypical, enlarged lymphocytes admixed with smaller lymphocytes, neutrophils and eosinophils (H&E ×400). (e) The infiltrate showed positive CD4 immunoreactivity (CD4 stain; ×40). (f) Atypical, large lymphocytes corresponded with CD30+ cells (CD30 stain; ×400). (g) Detection of the (4q12) deletion by interphase fluorescence in situ hybridization (FISH) in peripheral blood cells. Loss of red signal indicating fusion of FIP1L1-PDGFRα. (h) FIP1L1-PDGFRα fusion gene was not detected in T cells from cutaneous LyP lesion by FISH.
chromosome band comprising \( \text{LNX, CHIC2 and PDGFR} \) genes leading to a \( \text{FIP1L1-PDGFR} \) rearrangement was detected by fluorescence in situ hybridization (FISH) in peripheral blood cells (Fig. 1g). The deletion was present in eosinophils (46%), mast cells (100%) and granulocytes (45%) analysed from peripheral blood isolated populations. This led to the diagnosis of hypereosinophilic syndrome secondary to \( \text{FIP1L1-PDGFR} \) myeloid neoplasm. The presence of \( \text{FIP1L1-PDGFR} \) fusion gene was analysed by FISH in skin biopsy specimens of LyP. No individual cells were found to bear the translocation (Fig. 1h).

Treatment with imatinib mesilate (100 mg/day) was prescribed in February 2012. Regression of the cutaneous lesions and a rapid response of both haematological profile and LyP lesions was achieved and dosage was progressively tapered. After 58 months of treatment, the patient remains asymptomatic on a maintenance dosage of 100 mg/week (Fig. S11).

DISCUSSION

Characteristically, LyP is manifested by recurrent development of papulo-nodular lesions that undergo spontaneous regression after weeks or months. Many different therapeutic options have been proposed; nevertheless, after treatment discontinuation, relapses tend to occur (1) and no therapy has proven to alter the course of the disease nor prevent LyP-associated lymphomas.

Since the original description, 11 cases of LyP associated with idiopathic HES have been reported (2–8). The associated HES corresponded to M-HES and specifically to patients presenting the \( \text{FIP1L1-PDGFR} \) fusion gene, the most well-characterized molecular defect leading to hypereosinophilia (9). This subset of HES is characterized by splenomegaly, elevated serum B12 and tryptase levels, myeloproliferation and tissue fibrosis. Patients usually show a dramatic response to imatinib, which targets these genes (10).

The mechanisms implicated in the concurrent development of M-HES and LyP remain obscure. Clonal T cells bearing the \( \text{FIP1L1-PDGFR} \) rearrangement have been identified in some patients with \( \text{PDGFR} \)-associated HES, moreover, cases associating M-HES and T-cell lymphoblastic lymphoma in which both disorders carried the same \( \text{FIP1L1-PDGFR} \) rearrangement have been reported (11, 12). Conversely, a non-LyP CD30+ clonal T-cell proliferation associated with non-\( \text{FIP1L1-PDGFR} \) HES has been described recently, supporting the role of HES in the development of a clonal T-cell proliferations (13). A “multilineage clonal population” has also been postulated as the most likely explanation for the M-HES-LyP association (14). However, in our case we have been unable to demonstrate the presence of the specific translocation in cutaneous infiltrates of LyP lesions. The possibility that the neoplastic population bearing the \( \text{FIP1L1-PDGFR} \) gene fusion could be beyond the threshold of FISH detection, although improbable, cannot be disregarded. Therefore, the possibility that independent genetic events may engender this association cannot be excluded.

Since 2003, imatinib was prescribed in 7 cases of M-HES associated with LyP (Table S1'). In 4 of these, the \( \text{FIP1L1-PDGFR} \) fusion gene was demonstrated. A rapid regression of the cutaneous lesions was noted and a persistent, complete clinical, haematological and molecular remission was achieved (4, 6). No recurrences of LyP have been observed after variable follow-up periods. In our case, no new lesions have developed after a 5-year follow-up period.

The mechanisms implied in this constant response have not been elucidated. This parallel effect in both LyP and M-HES has not been observed in cases previously treated with regimes not including imatinib (2, 3). These observations could suggest that tyrosine kinase-mediated mechanisms play a role in the development of LyP. Furthermore, the possibility that this therapeutic effect could be a phenomena not restricted to the subset of LyP patients associated with M-HES has not been evaluated.
