Malassezia yeasts may be a trigger factor for atopic dermatitis. Following the recent reclassification of the genus, the presence of specific IgE antibodies was examined in the sera of patients with atopic dermatitis (n = 223), pityriasis versicolor (n = 83), seborrheic eczema (n = 50) and hymenoptera allergy (n = 39) and in controls without skin diseases (n = 50). In addition to using the commercially available radioallergosorbent test (RAST) for Pityrosporum orbiculare couplings were also made against the reference strains for M. furfur and M. sympodialis. To characterize the specificity and molecular weight of corresponding epitopes identical material was used for production of an immunoblot. Despite high total levels of IgE, controls and patients with pityriasis versicolor showed no specific IgE antibodies. Six patients (12%) with seborrheic eczema were positive while 78 patients (35%) with atopic dermatitis had specific IgE antibodies in higher RAST classes that differed between the Malassezia species. The molecular weights of the main antigens of M. sympodialis and M. furfur were determined to be 15, 22, 30, 37, 40, 58, 79, 92, 99 and 124 kDa and 15, 25, 27, 43, 58, 92, 99 and 107 kDa, respectively. Evaluated according to the location of their disease, patients with head and neck lesions most frequently showed Malassezia-specific IgE antibodies. However, there were differences between the Malassezia species tested, the previously used strain P. orbiculare being assignable to the species M. sympodialis. Key words: Malassezia yeasts; IgE antibodies; atopic dermatitis; immunoblot.

Yeasts of the genus Malassezia (previously Pityrosporum) belong to the resident flora of human skin; in addition, they play an important role in the pathogenesis of diseases such as pityriasis versicolor (PV), seborrheic eczema (SE) and Malassezia folliculitis (1–4). Detection of the high-affinity FcER-1 receptor and the low-affinity FcER-II/CD23 receptor on Langerhans cells pointed to the importance of microbial antigens in the pathogenesis of atopic dermatitis via IgE-mediated mechanisms (5). In this connection, two micro-organisms have been particularly emphasized: Staphylococcus aureus and the lipophilic yeasts Pityrosporum ovale/lobiculare (6–13). Pityrosporum yeasts are thought to be mainly involved in the pathogenesis of so-called head and neck dermatitis in younger patients (6, 11, 12). Especially in this patient group anti-Pityrosporum IgE antibodies were found, and 15–65% of these persons had positive skin tests with Pityrosporum extracts (7, 14). The possible relevance of these data was supported by the results of a controlled study in which 14 patients suffering from head and neck dermatitis improved during systemic antymycotic therapy with ketoconazole, while 5 with generalized skin lesions did not (15). Some of these studies were based on a radioallergosorbent test (RAST) against P. orbiculare developed by Pharmacia (Upsala, Sweden) and still available as ImmunoCAP under the labelling “m 70” (10, 13). According to the manufacturer, this test uses the strain 42132 from the American Type Culture Collection (ATCC) which is stored there under the name P. orbiculare/M. furfur.

During the last decade, molecular biological methods have revealed a similarity between Pityrosporum and Malassezia but for historical reasons the term Malassezia takes priority. Furthermore, the genus Malassezia has been extended: in addition to the known species M. furfur and M. pachydermatis, the species M. sympodialis was described in 1990, followed by M. globosa, M. obtusa, M. restricta and M. slooffiae in 1996 (4). Biochemical methods are now available for their differentiation (16–18).

Because many workers who investigated the importance of Malassezia/Pityrosporum in atopic eczema did not use reference strains and those tested are often no longer accessible, the question arises how to categorize antigens known as P. ovale/lobiculare according to today’s classification. Therefore, the present study compared special couplings against the reference strains for M. furfur (CBS 1878) and M. sympodialis (CBS 7222) with the commonly used commercial test. M. sympodialis was chosen because it probably belongs to the Malassezia species most frequently encountered on human skin (3).

Molecular weights and specificity of the antigens were characterized by means of a newly developed immunoblot. Furthermore, the possible relationship between head/neck/face locations of atopic dermatitis (AD) and Malassezia-specific antibodies was investigated.

MATERIAL AND METHODS

Patients

Serum samples were analyzed from patients with AD (n= 223; 82 males, 141 females; mean age 34.4 years), SE (n= 50; 36 males, 14
females; mean age 36.4 years), PV (n = 83; 47 males, 36 females; mean age 37 years) and hymenoptera allergy (HA) (n = 39; 18 males, 21 females; mean age 41.3 years) and from controls with healthy skin (HC) without clinically relevant signs of allergic rhinitis or bronchial asthma (n = 50; 34 males, 16 females, mean age 38.9 years). Diagnosis of AD was based on the criteria of Hanifin and Rajka (19); all patients with AD, SE and PV showed acute exacerbation of their disease. None of the selected persons had recently undergone topical treatment with corticoids. According to the location of their disease, patients with AD were divided into the following groups: (i) head/neck/face; (ii) extremities (flexural eczema, atopic hand/foot eczema, generalized affiliction of the extremities); and (iii) multifocal involvement of the body. According to their serum IgE value, persons with healthy skin were grouped into 2 categories: <120 and >120 kU/l (elevated level).

Determination of specific IgE antibodies against M. furfur, M. sympodialis and P. orbiculare

In addition to using the commercially available RAST for P. orbiculare, couplings were made against the reference strains for M. furfur (CBS 1878) and M. sympodialis (CBS 7222). Yeast cells harvested after 4 days growth at 30°C on m-Dixon agar (3) were immediately frozen at 80°C, lyophilized (speed-vac; Bachhofer, Germany) and sent to Pharmacia for coupling. A 4-day growth period was strictly adhered to because longer growth may result in loss of particular antigen regions (20). A patient serum which showed high RAST classes for all 3 antigens served as a control and was used repeatedly in the assays. The evaluation was made according to the RAST classes defined by Pharmacia (21). Furthermore, the total IgE level was measured in each patient by means of the Pharmacia ImmunoCAP system RAST and the inhalant allergen diagnostic test SX1 (Pharmacia) was performed in order to reveal possible atopic disposition.

Typing of strain ATCC 42132 "P. orbiculare"

The strain ATCC 42132, defined as P. orbiculare, was purchased from the ATCC (Rockville, MD, USA) and differentiated using the following methods: morphology of the culture; micromorphology after 10 days of growth on modified m-Dixon agar; catalase reaction and Tween assimilation according to Guilhot et al. (16); cremophor EL assimilation; esculin splitting; production of ethyl esters; and production of pigment according to Mayser and co-workers (17, 18, 22).

P.o.: Pityrosporum orbiculare; M.s.: Malassezia sympodialis; M.f.: Malassezia furfur; SE: seborrheic eczema; AD: atopic dermatitis; HA: hymenoptera allergy; PV: Pityriasis versicolor.

* Controls with healthy skin and without clinically relevant signs of allergic rhinitis or asthma, but with increased total IgE (>120 kU/l) and partially positive inhalant allergen test, possibly indicating an atopic constitution.

RESULTS

Rast

The results obtained with the RAST examinations are shown in Table I. The individual groups did not show significant differences with regard to total IgE (Mann–Whitney test), but varied considerably in terms of specific IgE antibodies to Malassezia/Pityrosporum.

The largest number of positive results was found in patients with AD (78; 35%), as against 12% in patients with SE and 8% in those with HA. Although patients with PV have their...
skin colonized with *M. furfur*, none was demonstrated to be sensitized in the RAST. The absolute level of total IgE in 1 patient was correlated with the demonstration of specific antibodies, but not all patients with a high total IgE value were found to be sensitized.

The correlation coefficient between total IgE level and occurrence of *Malassezia/Pityrosporum*-specific IgE antibodies was $r = 0.496$ ($p < 0.05$) for *P. orbiculare*, $r = 0.534$ ($p < 0.05$) for *M. furfur* and $r = 0.485$ ($p < 0.05$) for *M. sympodialis*.

Differences in the type and extent of sensitization were also found among the *Malassezia/Pityrosporum* yeasts. *M. sympodialis* ($n = 79$) and *P. orbiculare* ($n = 75$) were almost equally positive, while the frequency of sensitization to *M. furfur* ($n = 62$) was lower. Approximately 64% of all positive sera ($n = 87$) were positive for all 3 yeasts ($n = 56$), 16% for *P. orbiculare* and *M. sympodialis* ($n = 14$) and 6% for *M. sympodialis* and *M. furfur* ($n = 5$); however, none were positive for *P. orbiculare* and *M. furfur* (Table 1).

The 223 patients with AD divided into subgroups according to the location of their disease showed multifocal involvement of the body in 21% of cases, lesions predominantly on the arms in 38% of cases and lesions in the head/neck region in 41% of cases (Fig. 1). A similar division of the 78 patients with AD in whom the RAST had revealed sensitization to *Malassezia/Pityrosporum* yeasts shows that the relative proportion of patients with involvement of the extremities only was less than that with generalized affliction or with head/neck location (10%, 34% and 55%, respectively) (Fig. 2).

**Differentiation of ATCC 42132**

All the tests performed suggested that the strain ATCC 42132 “*P. orbiculare*” belongs to the species *M. sympodialis*.

**Immunoblot results**

The immunoblot developed showed a variety of antigens for *M. sympodialis* (27 bands) and *M. furfur* (27 bands) in the 40 patient sera examined. The molecular weights of the most important bands (present in > 5 different sera) were 15, 22, 30, 37, 40, 58, 79, 92, 99 and 124 kDa for *M. sympodialis* and 15, 25, 27, 43, 58, 92, 99 and 107 kDa for *M. furfur*. The results of the immunoblot are shown in Fig. 3. No bands were demonstrated on examination of the negative control (RAST class 0, total IgE level 12 kU/l) and the sera from patients with SE (2 patients) and PV (1).

In the homologous inhibition test high concentrations of the corresponding homologous extract were required for extinction of the specific bands. The patterns were only reduced by concentrations >50 mg/ml. The heterologous inhibition test was therefore performed with higher concentrations of the extract to detect possible cross-reactions of the antibodies. Pre-incubation of *M. sympodialis*-positive serum with *M. furfur* extract (10–200 mg/ml) caused no change in, or extinction of, the bands between 15 and 124 kDa. In contrast, extinction did result from pre-incubation of *M.
furfur-positive sera with *M. sympodialis* independent of the amount of heterologous substrate. The clear band at 15 kDa disappeared after addition of 10 mg/ml extract, indicating a possible cross-reaction of the antibodies.

**DISCUSSION**

This study is one of the first to determine IgE-mediated sensitization to *Malassezia/Pityrosporum* yeasts using antigen material according to the new classification of these yeasts. Reference strains for *M. furfur* (CBS 1878) and *M. sympodialis* (CBS 7222) were used and, for comparison, the commercially available test of Pharmacia, which uses *P. orbiculare/M. furfur* (ATCC 42132) as the antigen source, was also utilized. A culture period of 4 days was chosen because examinations by Zargari et al. (20) had shown that the spectrum of allergens is essentially dependent on the duration of culture.

Sensitization of the immediate reaction type was demonstrated in 87 of 445 sera (19.6%), with extents varying among the 3 antigens and patient/control groups. In >64% of positive sera (56/87) all 3 antigen sources (*M. furfur, M. sympodialis* and *P. orbiculare/M. furfur*) were positive, suggesting group antigens for IgE antibodies within the genus *Malassezia*. However, the frequency of sensitization to *M. furfur* (CBS 1878) was lower than that achieved with the 2 other test antigens (64, vs. 79 for *M. sympodialis* and 75 for the commercial test), and the RAST classes were often lower. The test results for *M. sympodialis* were highly correlated with those obtained from the commercial test, which is based on *P. orbiculare/M. furfur* (ATCC 42132). Apart from the 56 sera in which sensitization to all 3 antigen sources was demonstrated, specific antibodies to *P. orbiculare/M. furfur* were detected in another 14 cases. This result can be explained by biochemical characterization of the strain ATCC 42132 which is the basis of the commercial test. Currently available methods (16–18) show that the strain ATCC 42132 named *P. orbiculare/M. furfur* can be classified as *M. sympodialis*. Therefore, a test system based on *M. sympodialis* is more suitable for screening for immediate-type sensitization to *Malassezia* yeasts than a system based on *M. furfur*, all the more so as the former is more frequently observed on human skin than the latter (3). However, no final recommendation can be made because of the absence of test systems and data for the other recently described species (*M. globosa, M. obtusa, M. restricta* and *M. slooffiae*). To assess their actual importance, epidemiological details for these *Malassezia* species on healthy and diseased skin are required.

Although *Malassezia* species belong to the resident skin flora and are normally found there after puberty (4), it appears clinically remarkable that none of the 50 persons with clinically healthy skin had demonstrable IgE antibodies to these yeasts, even though 33 had elevated levels for serum IgE and 15 had a positive SX1 test as a marker for atopic constitution. However, in diseases where *Malassezia* yeasts play a pathogenic role and are found in higher numbers on the skin, such as PV or SE, sensitization was found either rarely (SE, 12%) or not at all (PV, 83 patients) despite occasionally very high levels of total IgE. It appears that other mechanisms are involved in the pathogenesis of these diseases (4, 22, 24–26). Among the groups selected, patients with AD were most frequently sensitized (78/223; 34%). However, allergic/atopic disposition is not necessarily a prerequisite for sensitization. Of the 39 patients with HA only 2 were weakly sensitized (8%), although the SX1 test indicating atopic disposition was positive nearly as often as in the group of atopies (72% vs. 78%). Moreover, the frequency of sensitization in AD was markedly correlated with the location of the disease, especially in those with head/neck/face location (*p* < 0.05). As Malassezia yeasts occur primarily in these body areas, they might be a trigger factor. It is possible that skin colonization with *Pityrosporum/Malassezia* yeasts leads to ongoing immunostimulation in patients with AD (27–29). Increased presentation of the antigen is thought to result from inflammatory processes in these areas, augmented by chronic itching and scratching and followed by elevated IgE production of specific antibodies (5, 12). This sensitization might influence the further course of the disease, particularly as in *in vitro* studies have shown that extracts of *P. ovale* can markedly increase IgE synthesis and release of interleukin-4 and interleukin-10 in patients with AD (12, 26). Furthermore, atopics showed specific IgE antibodies to *Pityrosporum/Malassezia* significantly more often than other patients, while total IgE levels were elevated (*p* < 0.05). This connection was also noted in previous studies (8–11, 14). According to Waerstedt & Hjorth (6), unspecific sensitization as an expression of general hyperreagibility is less likely in view of the finding that patients with respiratory allergy are seldom sensitized to *Malassezia* antigens. Also, patients with a head/neck disease location had more frequently positive results (10, 12, 14).

In children, sensitization to *Malassezia* yeasts was correlated with increased activity of AD and more nocturnal itching (13). In particular, the effective antimycotic treatment of lesions in the head/neck region is an argument in favor of the pathogenetic importance of these yeasts (15, 30). However, these findings could not be confirmed in all studies (31). Interesting results were also obtained by determining the antibody-binding epitopes of *Malassezia* yeasts. Both qualitative and quantitative agreements between the RAST and immunoblotting were good. In our study, the following epitopes with a high binding frequency were detected: proteins with molecular weights of 15, 25, 27, 43, 58, 92, 99 and 107 kDa for *M. furfur* CBS 1878 and 15, 22, 30, 37, 40, 58, 79, 92, 99 and 124 kDa for *M. sympodialis* CBS 7222. The demonstrated epitopes are not consistent with the binding sites reported in the literature (29, 32–34), but again a question arises concerning the identity of the species. In *P. orbiculare* Zargari et al. (32) detected IgE-binding proteins with molecular weights of 37 and 67 kDa. Johansen & Karlström (34) demonstrated proteins with molecular weights of 86, 76, 67, 28, 17 and 13 kDa by means of an immunoblot technique and sodium dodecyl sulfate-polyacrylamide gel electrophoresis, 67 kDa being the major antigen determinant. Lintu et al. (33) emphasized particularly the importance of the 9, 20 and 96 kDa binding regions.

In summary, it was shown that patients with manifest AD are more often sensitized to *Malassezia* yeasts than other patient groups and healthy persons. Furthermore, it was confirmed that patients with a head/neck disease location are most frequently sensitized to *Malassezia* yeasts. The immunoblot results are indicative of a variety of group antigens between *M. furfur* and *M. sympodialis*, but antigen material...
obtained from *M. sympodialis* is most suitable for screening tests. Based on these findings, extended examinations of prick, intracutaneous and atopy patch tests could help to distinguish a group of atopics who might benefit from antymycotic therapy.
