Objective: We report here a rare case of anterior superior iliac spine avulsion fracture that presented initially as meralgia paraesthetica.

Case report: A 14-year-old male sprinter presented with anterior superior iliac spine avulsion fracture, which was not observed on initial plain radiograph of the hip, but was diagnosed by ultrasound. Both clinical presentations and electrophysiological studies indicated meralgia paraesthetica. The lateral femoral cutaneous nerve of the thigh was probably compressed by an inguinal haematoma resulting from sartorius muscle strain, which was detected on musculoskeletal ultrasound. Computed tomography of the pelvis confirmed anterior superior iliac spine avulsion fracture.

Conclusion: Meralgia paraesthetica in adolescents can be due to anterior superior iliac spine avulsion fracture. Sonography is a valuable tool for screening for muscular haematoma and occult fractures, which may allow clinicians to diagnose the nature of the muscle injury, and thus guide the most appropriate therapeutic strategy.

Key words: anterior superior iliac spine; avulsion fracture; meralgia paraesthetica; musculoskeletal ultrasound; adolescence.

INTRODUCTION

Meralgia paraesthetica is an entrapment neuropathy of the lateral femoral cutaneous nerve, resulting in a painful, burning, numb sensation in a skin patch over the anterior and lateral thigh (1). Rare initial presentation of anterior superior iliac spine (ASIS) fracture as meralgia paraesthetica has been reported (2–4). We describe here an adolescent sprinter with an ASIS avulsion fracture presenting clinically as meralgia paraesthetica.

CASE REPORT

A 14-year-old boy presented to our clinic because of right anterolateral thigh numbness for 3 days. The patient had been well 3 days earlier, and symptoms of meralgia paraesthetica developed after a running competition at school. The initial X-ray scan of the right hip (anterior-posterior view), obtained immediately after the injury in the emergency department of a local hospital, was unremarkable (Fig. 1). Physical examination revealed mild tenderness around the ASIS and paraesthesia over the right anterolateral thigh under sensory testing of light-touch and pin-prick. Straight leg raising was normal. No pain was noted during passive or active range of motion of his right hip joint. The patient was able to walk with little discomfort with a mild limping gait.

An ultrasound machine (MicroMaxx, SonoSite, FujiFilm, USA) with a 10-5 MHz linear-array transducer was utilized for scanning the right inguinal area. In transverse view, a mixed hyperechoic and hypoechoic haematoma was noted just medial and inferior to the tender area of the right ASIS and beneath the right internal and external oblique abdominal muscles. The haematoma, measuring 3.8 cm in diameter, had no internal increased vascularity (Fig. 2). Along the axis of the sartorius tendon, a separated bony fragment with minimal displacement was detected over the tender point of his right ASIS, measuring 1.6 cm (Fig. 3). Ultrasound indicated avulsion fracture of the ASIS and a muscular haematoma at the groin area.

Fig. 1. Initial X-ray of the right hip (anterior–posterior view), obtained immediately after the injury, was interpreted as normal.
ASIS fracture presenting as meralgia paraesthetica

The fracture was confirmed by a computed tomography (CT) scan without contrast medium. A bony fragment was seen in the inferior part of the right ASIS with minimal displacement in the axial (Fig. 4A) and coronal views (Fig. 4B). A possible haematoma with increased CT signals was detected 1 cm caudal to the axial plane of the fracture (Fig. 4C). Ten days after the injury, nerve conduction studies performed in both legs did not reveal any abnormality, except for the absence of sensory nerve action potential in the right lateral femoral cutaneous nerve of the thigh, which was compatible with the clinical presentation of meralgia paraesthetica (Table I).

After the fracture was diagnosed, non-surgical 6-week conservative treatment was recommended by the orthopaedist.

DISCUSSION

The clinical presentation of meralgia paraesthetica in this case was a rare presentation of ASIS avulsion fracture. One cadaver study suggested that the lateral femoral cutaneous nerve is most susceptible to mechanical trauma located posterior, anterior, or medial to the ASIS; that is, at the origin of the sartorius and tensor fascia lata muscles (1). Although many cases of meralgia paraesthetica are due to entrapment of the inguinal ligament, other mechanisms, such as traction force resulting from bone grafting (5) or bony fragment (4) and haematoma or oedema irritation (2, 3), have been proposed. In the present...
case, the lateral femoral cutaneous nerve of the thigh was probably compressed by an inguinal haematoma due to strain on the sartorius muscle, which highlighted that the diagnosis was made using ultrasound.

Avulsion fracture of the ASIS is an uncommon pelvic apophyseal injury, typically occurring in adolescents after a sudden contraction of a muscle attached to the growing apophyses (6). Depending on the muscle affected, this fracture can be categorized into sprinting (sartorius) type or swinging (tensor fascia lata) type, with the sprinting type accounting for most cases (7). Sports that result in this injury include soccer, athletics, gymnastics, tennis, fencing, basketball, and baseball (6, 7). A delay in treatment of the avulsion fracture of the ASIS can cause painful non-union, limited sports performance, and even long-term disability. Determining the timing of the injury is difficult, and diagnosis of the avulsion fracture may be missed in conventional plain X-ray scan of the pelvis (8). In the present case, if the CT had been carried out immediately after the injury, the fracture would have been diagnosed, which suggests that plain X-ray may not be sufficient for detecting occult apophyseal injuries. Conservative treatment in cases of minimal displacement show favourable outcomes (6, 9), while surgical intervention should be considered in cases of extensive displacement.

In conclusion, the clinical presentation of meralgia paraesthetica in adolescent athletes may be indicative of ASIS avulsion fracture. Sonography may help clinicians to screen for muscular haematoma and occult fractures, which may allow them to diagnose the nature of the muscle injury, thus guiding the most appropriate therapeutic strategy.
